Abstract

This paper analyses emerging market (EM) currency co-movement, during different periods of global uncertainty. After stratifying the data for periods of high and low uncertainty using the CBOE Volatility Index (VIX), we use Dynamic Conditional Correlation (DCC), proposed by Engle (2002) to compare co-movement during these periods to the sample average. The aim is to uncover crucial dynamics between these currencies, specifically between the South African Rand (ZAR) and other currencies. The main purpose for the study is that these correlations directly influence investors and currency traders. Using EM currency data from four groups of economies from 2002 to 2018, the paper finds that find that conditional correlations increase significantly following the financial crisis. However, we do not find significant differences during periods of high and low uncertainty. Currency traders should thus look to other factors than the VIX when making EM currency investment decisions.

1. Introduction

The purpose of this paper is to model the co-movement between EM currencies, during differing periods of uncertainty. We employ Engle (2002)'s Dynamic Conditional Correlation (DCC) model, to describe time-varying correlation and volatility. The main aim of the study to see whether currencies are more closely correlated during heightened global uncertainty. However more generally, the paper discusses the relationships between ZAR and other groups of EM currencies. Our focus is on the *ZAR's* correlation with the rest of the currencies in our sample. Naturally, our question has important consequences for currency traders, which provides good motivation to investigate the topic in more detail. For instance, if the ZAR is strongly positively (negatively) correlated with the Brazilian Real (BRL) when the VIX is higher than usual, then it would be sensible to sell (buy) BRL, as a

diversification strategy.

The layout of the rest of this paper is as follows: section 2 discusses relevant literature concerning financial contagion and currency correlation. Section 3 discusses the data used and section 4 describes the methodology used to model currency co-movement. Section **??** reports the results and section 6 concludes and provides some recommendations to fund managers.

2. Literature review

3. Data

The data includes EM currencies from 2002 to 2018. The currencies are grouped into four categories, namely BRICS, Asia, South America and Eastern Europe.[1] Although the data is of daily frequency, we calculate the weekly returns to avoid the noise present in currency returns. Note that given the use of currency data, a positive return is synonymous with "depreciation", whereas a negative return is synonymous with a "depreciation". Furthermore, all currencies are measured relative to the United States dollar (USD).

Table 7.1 in the appendix reports the summary statistics (mean and standard deviation) for all of the currencies in our sample.[2] The summary statistics suggests that currency values (quotes) relative to the USD vary greatly, whereas the average weekly returns (and their corresponding standard deviations) are generally very low. This makes sense given that the weekly return calculation strips out the noise present in daily returns.

In this paper, we stratify the data according to differing periods of uncertainty. To gain an idea of how this looks in practice, see figure 3.1 which plots the VIX over the full sample period. The black lines distinguish the top and bottom quintiles from the rest, which is crucial for our calculations. Specifically, all observations above the black line are classified as "high uncertainty" and all observations below the black line are classified as "low uncertainty". We make this explicit by shading the dates which are pulled by stratification. We then compare correlations during these periods with average correlations during the full sample period.

---

[1]This grouping convention is drawn from Katzke and Polakow (2017).

[2]Refer to table 7.2 in the appendix for the full list of currencies considered.
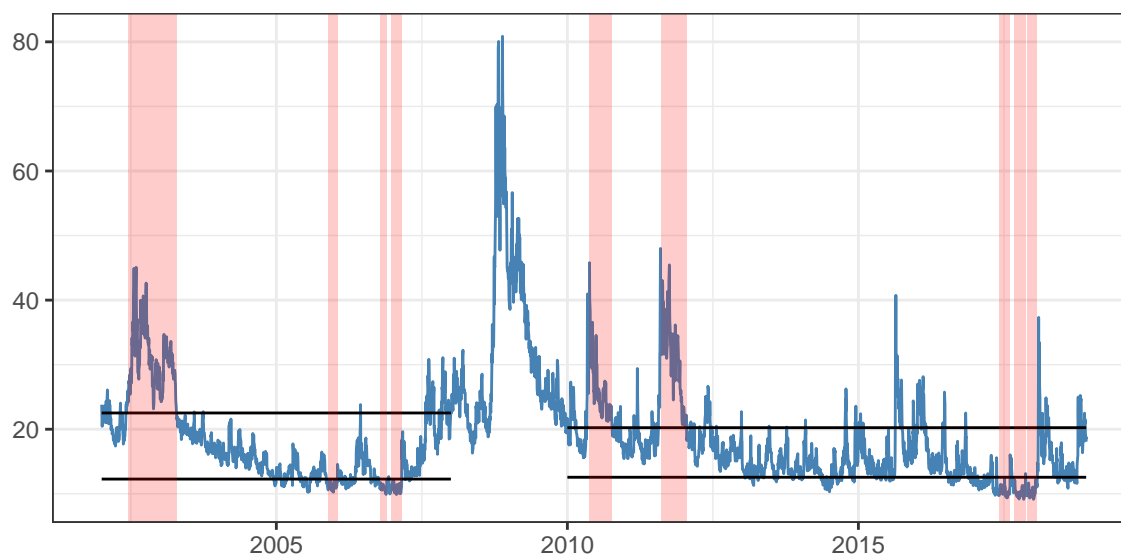

Figure 3.1: VIX

Figure 3.1 emphasises the spike in the VIX during the global financial crisis (GFC), which led to unprecedented effects on global capital markets. This motivates us to omit these dates from our analysis as we do not want this to bias our DCC estimates.

4. Methodology

This section discusses the theory behind the correlation estimates, namely DCC. We use the GARCH-DCC approach, first proposed by Engle (2002).[3] A major benefit of this method is that large correlation matrices can be estimated, given the flexibility of univariate GARCH processes. This is why Engle (2002)'s method is preferred for our correlation estimates. The GARCH-DCC approach is conducted by estimating univariate GARCH models after which the correlation estimate is computed. Hence, the process comprises two steps which are discussed in this section. Section 4.1 defines GARCH models, whereas section 4.3 discusses DCC estimation. Frequent reference is made to Engle (2002) throughout.

4.1. GARCH models

To generalise univariate GARCH models to the multivariate sphere is a simple task. Given the stochastic process of financial returns, x_t ($t = 1, 2, ...T$), with dimension $N \times 1$ and mean vector μ_t

---

[3]'GARCH' refers to generalized autoregressive conditional heteroskedasticity.

and given the information set I_{t-1}, we can write $x_t \,|\, I_{t-1}$ as follows:

$$x_t \,|\, I_{t-1} = \mu_t + \varepsilon_t, \tag{4.1}$$

where the residuals of the process are modelled as:

$$\varepsilon_t = H_t^{1/2} z_t. \tag{4.2}$$

$H_t^{1/2}$ above is an $N \times N$ positive definite matrix such that H_t is the conditional covariance matrix of x_t. z_t is an $N \times 1$ independent and identically distributed series, with a mean of zero and a variance of one.

4.2. DCC Models

As previously mentioned, DCC models offer a simple and more parsimonious means of doing multi-variate volatility modelling. In particular, it relaxes the constraint of a fixed correlation structure, which is assumed by the constant conditional correlation (CCC) model, to allow for estimates of time-varying correlation.

The DCC model can be defined as:

$$H_t = D_t.R_t.D_t. \tag{4.3}$$

Equation 4.3 splits the variance-covariance matrix into identical diagonal matrices (D_t) and an estimate of the time-varying correlation (R_t). Estimating R_t (which is the correlation matrix) requires it to be inverted at each estimated period, and thus a proxy equation is used:

$$\begin{aligned} Q_{ij,t} &= \bar{Q} + a\left(z_{t-1}z'_{t-1} - \bar{Q}\right) + b\left(Q_{ij,t-1} - \bar{Q}\right) \\ &= (1 - a - b)\bar{Q} + az_{t-1}z'_{t-1} + b.Q_{ij,t-1} \end{aligned} \tag{4.4}$$

Equation 4.4 has a similar structure to a GARCH(1,1) process, with non-negative scalars a and b.

Furthermore, $Q_{ij,t}$ is the unconditional (sample) variance estimate between series i and j and $\bar{Q}$ is the unconditional matrix of standardized residuals from each univariate pair estimate.

Next, we use equation 4.4 to estimate R_t (the conditional correlation matrix), which is expressed as:

$$R_t = diag(Q_t)^{-1/2}Q_t.diag(Q_t)^{-1/2}. \tag{4.5}$$

Equation 4.5 has bivariate elements:

$$R_t = \rho_{ij,t} = \frac{q_{i,j,t}}{\sqrt{q_{ii,t}.q_{jj,t}}} \tag{4.6}$$

The resulting DCC model is then formulated statistically as:

$$
\begin{aligned}
\varepsilon_t &\sim N(0, D_t.R_t.D_t) \\
D_t^2 &\sim \text{Univariate GARCH(1,1) processes } \forall \text{ (i,j), i} \neq \text{j} \\
z_t &= D_t^{-1}.\varepsilon_t \\
Q_t &= \bar{Q}(1 - a - b) + a(z_t' z_t) + b(Q_{t-1}) \\
R_t &= Diag(Q_t^{-1}).Q_t.Diag(Q_t^{-1})
\end{aligned}
$$

$$\tag{4.7}$$

5. Dynamic Conditional Correlations

Next we use the methodology discussed in section 4 to estimate the dynamic conditional correlations.[4] Our focus is on the bivariate correlation between ZAR and the rest of the currencies in the sample. However, in this section we only report the results for the BRICS economies. The full set of results is contained in the appendix.

Using the univariate GARCH methodology, figure 5.1 plots the conditional volatilities for all BRICS currencies for both periods.

---

[4]We omit China and Malaysia for Period 1 because their currencies were pegged to the USD until approximately 2005. Their inclusion induces zero returns for Period 1.
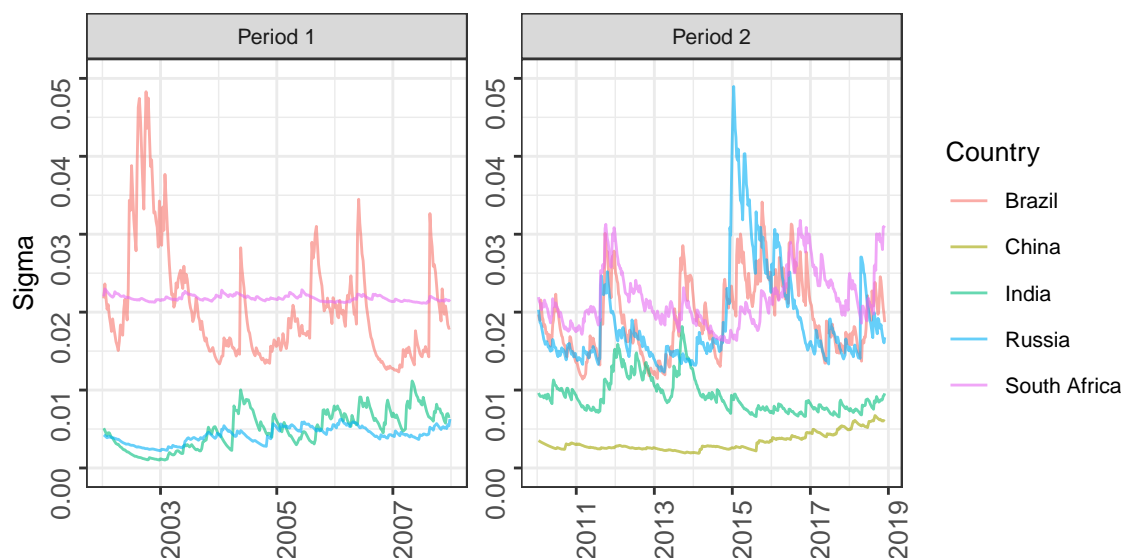

Figure 5.1: BRICS conditional volatility

Figure 5.1 suggests that prior to the financial crisis (Period 1), the BRL was the most volatile BRICS currency whereas the ZAR was the most stable of the group. However, the story changed somewhat in the post-crisis era (Period 2): the Chinese Renminbi (CNY), no longer pegged to the USD, remained the most stable currency of the group, whereas the ZAR and remaining BRICS currencies became markedly more volatile. The results suggest that the most volatile currency groupings are BRICS and South America.

Turning to the DCC estimations, figure 5.2 plots the ZAR's dynamic conditional correlation with the other BRICS currencies.
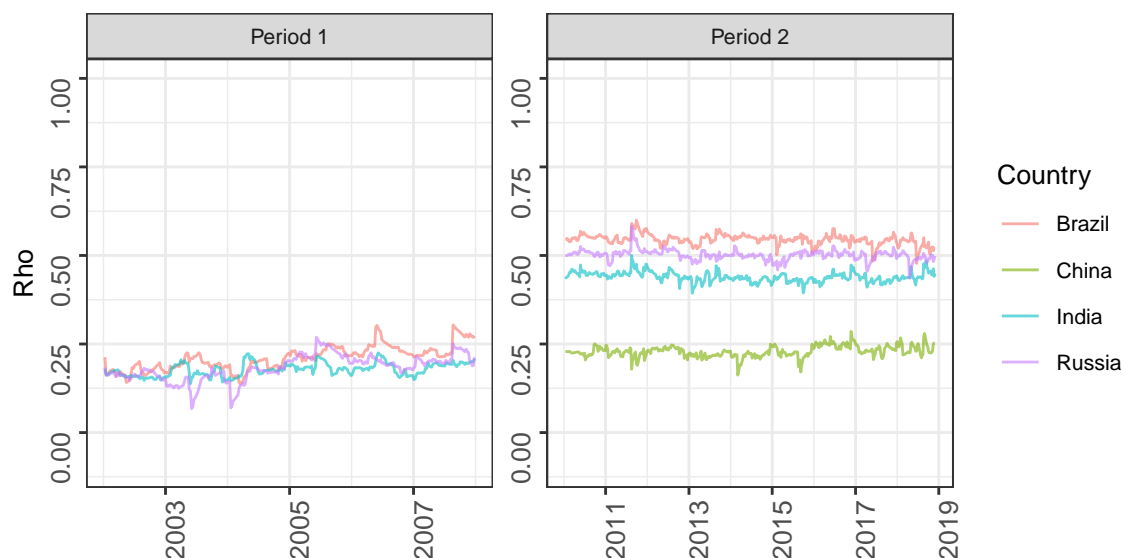

Figure 5.2: BRICS dynamic conditional correlation

The pre-crisis estimations suggest seemingly constant correlation over the period at approximately 0.25 (one might argue in favour of a slight increase in correlation in Period 1). Following the crisis, correlations doubled all except for the CNY which had recently switched to a flexible exchange rate regime. The plot clearly shows the ZAR being most highly correlated with the BRL, Russian Ruble (RUB) and Indian Rupee (INR), respectively. These three bivariate correlations hover around the 0.50 mark, which implies that a two per cent appreciation in the ZAR results in a one per cent appreciation in the BRL, RUB and INR, on average. This is indeed a high correlation.

An interesting note on the DCC results[5] is that Period 2 conditional correlations seem higher than Period 1. This could suggest a structural change in EM currency correlations following the financial crisis. * Discuss the QE effects on co-movement.

To see whether the correlations increase during times of heightened uncertainty, we plot the DCC estimations and overlay the dates which we consider as 'high-VIX' and 'low-VIX'. Figure 5.3 suggests that we should not downplay an increase in correlation during 'high-VIX' periods. This follows as eyeballing the figure could suggest that correlations creep up during more uncertain times.

---

[5]See the appendix (section 7).

Figure 5.3: BRICS dynamic conditional correlation

However, when calculating average sample correlations, as well as these correlations for high and low-VIX periods, we do not find significant differences in these periods.[6] Hence, we must conclude that the ZAR is *not* more closely correlated with other EM currencies when the VIX is in its top quintile (or in the bottom quintile, for that matter). What we do find, however, is that following the GFC, EM currencies became much more correlated than before.

6. Conclusion

[Conclusion to be written here.]

---

[6]Table 7.3 in the appendix contains the average pairwise correlations, for the full sample and during times of high and low uncertainty.
